# Chapter 3. Dictionaries and Sets

Python is basically dicts wrapped in loads of syntactic sugar.

—Lalo Martins, early digital nomad and Pythonista

We use dictionaries in all our Python programs. If not directly in our code, then indirectly because the <code>dict</code> type is a fundamental part of Python's implementation. Class and instance attributes, module namespaces, and function keyword arguments are some of the core Python constructs represented by dictionaries in memory. The <code>\_\_builtins\_\_.\_\_dict\_\_</code> stores all built-in types, objects, and functions.

Because of their crucial role, Python dicts are highly optimized—and continue to get improvements. *Hash tables* are the engines behind Python's high-performance dicts.

Other built-in types based on hash tables are set and frozenset. These offer richer APIs and operators than the sets you may have encountered in other popular languages. In particular, Python sets implement all the fundamental operations from set theory, like union, intersection, subset tests, etc. With them, we can express algorithms in a more declarative way, avoiding lots of nested loops and conditionals.

Here is a brief outline of this chapter:

- Modern syntax to build and handle dicts and mappings, including enhanced unpacking and pattern matching
- Common methods of mapping types
- Special handling for missing keys
- Variations of dict in the standard library
- The set and frozenset types
- Implications of hash tables in the behavior of sets and dictionaries

# What's New in This Chapter

Most changes in this second edition cover new features related to mapping types:

- <u>"Modern dict Syntax"</u> covers enhanced unpacking syntax and different ways of merging mappings—including the | and |= operators supported by dicts since Python 3.9.
- <u>"Pattern Matching with Mappings"</u> illustrates handling mappings with match/case, since Python 3.10.
- <u>"collections.OrderedDict"</u> now focuses on the small but still relevant differences between dict and OrderedDict—considering that dict keeps the key insertion order since Python 3.6.
- New sections on the view objects returned by dict.keys, dict.items, and dict.values: "Dictionary Views" and "Set Operations on dict Views".

The underlying implementation of dict and set still relies on hash tables, but the dict code has two important optimizations that save memory and preserve the insertion order of the keys in dict. "Practical Consequences of How dict Works" and "Practical Consequences of How Sets Work" summarize what you need to know to use them well.

#### NOTE

After adding more than 200 pages in this second edition, I moved the optional section <u>"Internals of sets and dicts"</u> to the <u>fluentpython.com</u> companion website. The updated and expanded <u>18-page post</u> includes explanations and diagrams about:

- The hash table algorithm and data structures, starting with its use in set, which is simpler to understand.
- The memory optimization that preserves key insertion order in dict instances (since Python 3.6).
- The key-sharing layout for dictionaries holding instance attributes—the dict of user-defined objects (optimization implemented in Python 3.3).

# Modern dict Syntax

The next sections describe advanced syntax features to build, unpack, and process mappings. Some of these features are not new in the language, but may be new to you. Others require Python 3.9 (like the | oper-

ator) or Python 3.10 (like match/case). Let's start with one of the best and oldest of these features.

## dict Comprehensions

Since Python 2.7, the syntax of listcomps and genexps was adapted to dict comprehensions (and set comprehensions as well, which we'll soon visit). A *dictcomp* (dict comprehension) builds a dict instance by taking key:value pairs from any iterable. Example 3-1 shows the use of dict comprehensions to build two dictionaries from the same list of tuples.

#### Example 3-1. Examples of dict comprehensions

```
>>> dial codes = [
... (880, 'Bangladesh'),
      (55, 'Brazil'),
. . .
      (86, 'China'),
. . .
      (91, 'India'),
      (62, 'Indonesia'),
      (81, 'Japan'),
      (234, 'Nigeria'),
      (92, 'Pakistan'),
. . .
       (7, 'Russia'),
       (1, 'United States'),
. . .
...]
>>> country dial = {country: code for code, country in dial codes}
>>> country dial
{'Bangladesh': 880, 'Brazil': 55, 'China': 86, 'India': 91, 'Indonesia': 62
'Japan': 81, 'Nigeria': 234, 'Pakistan': 92, 'Russia': 7, 'United States':
                                                                   0
>>> {code: country.upper()
      for country, code in sorted(country dial.items())
       if code < 70}
{55: 'BRAZIL', 62: 'INDONESIA', 7: 'RUSSIA', 1: 'UNITED STATES'}
```

- An iterable of key-value pairs like dial\_codes can be passed directly to the dict constructor, but...
- 2 ...here we swap the pairs: country is the key, and code is the value.
- Sorting country\_dial by name, reversing the pairs again, uppercasing values, and filtering items with code < 70.

If you're used to listcomps, dictcomps are a natural next step. If you aren't, the spread of the comprehension syntax means it's now more profitable than ever to become fluent in it.

## **Unpacking Mappings**

<u>PEP 448—Additional Unpacking Generalizations</u> enhanced the support of mapping unpackings in two ways, since Python 3.5.

First, we can apply \*\* to more than one argument in a function call. This works when keys are all strings and unique across all arguments (because duplicate keyword arguments are forbidden):

```
>>> def dump(**kwargs):
... return kwargs
...
>>> dump(**{'x': 1}, y=2, **{'z': 3})
{'x': 1, 'y': 2, 'z': 3}
```

Second, \*\* can be used inside a dict literal—also multiple times:

```
>>> {'a': 0, **{'x': 1}, 'y': 2, **{'z': 3, 'x': 4}} 
{'a': 0, 'x': 4, 'y': 2, 'z': 3}
```

In this case, duplicate keys are allowed. Later occurrences overwrite previous ones—see the value mapped to  $\times$  in the example.

This syntax can also be used to merge mappings, but there are other ways. Please read on.

## Merging Mappings with |

Python 3.9 supports using || and || = to merge mappings. This makes sense, since these are also the set union operators.

The | operator creates a new mapping:

```
>>> d1 = {'a': 1, 'b': 3}
>>> d2 = {'a': 2, 'b': 4, 'c': 6}
>>> d1 | d2
{'a': 2, 'b': 4, 'c': 6}
```

Usually the type of the new mapping will be the same as the type of the left operand— d1 in the example—but it can be the type of the second operand if user-defined types are involved, according to the operator overloading rules we explore in <a href="#">Chapter 16</a>.

To update an existing mapping in place, use  $\mid$  = . Continuing from the previous example, d1 was not changed, but now it is:

```
>>> d1
{'a': 1, 'b': 3}
>>> d1 |= d2
>>> d1
{'a': 2, 'b': 4, 'c': 6}
```

#### TIP

If you need to maintain code to run on Python 3.8 or earlier, the <u>"Motivation"</u> section of <u>PEP 584—Add Union Operators To dict</u> provides a good summary of other ways to merge mappings.

Now let's see how pattern matching applies to mappings.

# Pattern Matching with Mappings

The match/case statement supports subjects that are mapping objects. Patterns for mappings look like dict literals, but they can match instances of any actual or virtual subclass of

```
collections.abc.Mapping.1
```

In <u>Chapter 2</u> we focused on sequence patterns only, but different types of patterns can be combined and nested. Thanks to destructuring, pattern matching is a powerful tool to process records structured like nested mappings and sequences, which we often need to read from JSON APIs and databases with semi-structured schemas, like MongoDB, EdgeDB, or PostgreSQL. <u>Example 3-2</u> demonstrates that. The simple type hints in get\_creators make it clear that it takes a dict and returns a list.

**Example 3-2. creator.py:** get\_creators() **extracts names of creators** from media records

- Match any mapping with 'type': 'book', 'api' :2, and an 'authors' key mapped to a sequence. Return the items in the sequence, as a new list.
- Match any mapping with 'type': 'book', 'api' :1, and an 'author' key mapped to any object. Return the object inside a list.
- Any other mapping with 'type': 'book' is invalid, raise ValueError.
- Match any mapping with 'type': 'movie' and a 'director' key mapped to a single object. Return the object inside a list.
- 6 Any other subject is invalid, raise ValueError.

Example 3-2 shows some useful practices for handling semi-structured data such as JSON records:

- Include a field describing the kind of record (e.g., 'type':
   'movie')
- Include a field identifying the schema version (e.g., 'api': 2') to allow for future evolution of public APIs
- Have case clauses to handle invalid records of a specific type (e.g., 'book'), as well as a catch-all

Now let's see how get creators handles some concrete doctests:

```
>>> b1 = dict(api=1, author='Douglas Hofstadter',
           type='book', title='Gödel, Escher, Bach')
>>> get creators(b1)
['Douglas Hofstadter']
>>> from collections import OrderedDict
>>> b2 = OrderedDict(api=2, type='book',
          title='Python in a Nutshell',
           authors='Martelli Ravenscroft Holden'.split())
>>> get creators(b2)
['Martelli', 'Ravenscroft', 'Holden']
>>> get creators({'type': 'book', 'pages': 770})
Traceback (most recent call last):
ValueError: Invalid 'book' record: {'type': 'book', 'pages': 770}
>>> get creators('Spam, spam, spam')
Traceback (most recent call last):
ValueError: Invalid record: 'Spam, spam'
```

Note that the order of the keys in the patterns is irrelevant, even if the subject is an OrderedDict as b2.

In contrast with sequence patterns, mapping patterns succeed on partial matches. In the doctests, the b1 and b2 subjects include a 'title' key that does not appear in any 'book' pattern, yet they match.

There is no need to use \*\*extra to match extra key-value pairs, but if you want to capture them as a dict, you can prefix one variable with \*\* . It must be the last in the pattern, and  $**_{\_}$  is forbidden because it would be redundant. A simple example:

```
>>> food = dict(category='ice cream', flavor='vanilla', cost=199)
>>> match food:
...    case {'category': 'ice cream', **details}:
...         print(f'Ice cream details: {details}')
...
Ice cream details: {'flavor': 'vanilla', 'cost': 199}
```

In <u>"Automatic Handling of Missing Keys"</u> we'll study defaultdict and other mappings where key lookups via \_\_getitem\_\_ (i.e., d[key]) succeed because missing items are created on the fly. In the context of pattern matching, a match succeeds only if the subject already has the required keys at the top of the match statement.

The automatic handling of missing keys is not triggered because pattern matching always uses the d.get(key, sentinel) method—where the default sentinel is a special marker value that cannot occur in user data.

Moving on from syntax and structure, let's study the API of mappings.

# Standard API of Mapping Types

The collections.abc module provides the Mapping and MutableMapping ABCs describing the interfaces of dict and similar types. See Figure 3-1.

The main value of the ABCs is documenting and formalizing the standard interfaces for mappings, and serving as criteria for isinstance tests in code that needs to support mappings in a broad sense:

```
>>> my_dict = {}
>>> isinstance(my_dict, abc.Mapping)
True
>>> isinstance(my_dict, abc.MutableMapping)
True
```

#### TIP

Using isinstance with an ABC is often better than checking whether a function argument is of the concrete dict type, because then alternative mapping types can be used. We'll discuss this in detail in <a href="#">Chapter 13</a>.

MutableMapping

To implement a custom mapping, it's easier to extend collections. UserDict, or to wrap a dict by composition, instead of subclassing these ABCs. The collections. UserDict class and all concrete mapping classes in the standard library encapsulate the basic dict in their implementation, which in turn is built on a hash table. Therefore, they all share the limitation that the keys must be *hashable* (the values need not be hashable, only the keys). If you need a refresher, the next section explains.

#### What Is Hashable

Here is part of the definition of hashable adapted from the <u>Python</u> *Glossary*:

An object is hashable if it has a hash code which never changes during its lifetime (it needs a \_\_hash\_\_ () method), and can be compared to other objects (it needs an \_\_eq\_\_ () method). Hashable objects which compare equal must have the same hash code. $^2$ 

Numeric types and flat immutable types str and bytes are all hashable. Container types are hashable if they are immutable and all contained objects are also hashable. A frozenset is always hashable, because every element it contains must be hashable by definition. A tuple is hashable only if all its items are hashable. See tuples tt, tl, and tf:

```
>>> tt = (1, 2, (30, 40))
>>> hash(tt)
8027212646858338501
>>> tl = (1, 2, [30, 40])
>>> hash(tl)
Traceback (most recent call last):
   File "<stdin>", line 1, in <module>
TypeError: unhashable type: 'list'
>>> tf = (1, 2, frozenset([30, 40]))
>>> hash(tf)
-4118419923444501110
```

The hash code of an object may be different depending on the version of Python, the machine architecture, and because of a *salt* added to the hash computation for security reasons. The hash code of a correctly implemented object is guaranteed to be constant only within one Python process.

User-defined types are hashable by default because their hash code is their id(), and the  $\_eq\_()$  method inherited from the object class simply compares the object IDs. If an object implements a custom  $\_eq\_()$  that takes into account its internal state, it will be hashable only if its  $\_hash\_()$  always returns the same hash code. In practice, this requires that  $\_eq\_()$  and  $\_hash\_()$  only take into account instance attributes that never change during the life of the object.

Now let's review the API of the most commonly used mapping types in Python: dict, defaultdict, and OrderedDict.

## **Overview of Common Mapping Methods**

The basic API for mappings is quite rich. <u>Table 3-1</u> shows the methods implemented by dict and two popular variations: defaultdict and OrderedDict, both defined in the collections module.

Table 3-1. Methods of the mapping types dict, collections.defaultdict, and collection s.OrderedDict (common object methods omitted for brevity); optional arguments are enclosed in [...]

	dict	defaultdict	OrderedDict	
d.clear()	•	•	•	Remove all items
dconta ins(k)	•	•	•	k in d
d.copy()	•	•	•	Shallow copy
dcopy_ _()		•		Support for cop y.copy (d)
d.default _factory		•		Callable invoked bymi ssing_ to set missing valuesa
ddelit em(k)	•	•	•	del d [k] — remove item with key

d.fromkey	•	•	•	New
s(it, [in				mapping
itial])				from
				keys in
				iterable,
				with op-
				tional
				initial
				value
				(defaults
				to
				None)
d.get(k,	•	•	•	Get item
[defaul				with key
t])				k, re-
				turn de
				fault
				or None
				if
				missing
dgetit	•	•	•	d[k] —
em(k)				get item

(m, [**kw	•	•	•	d with items from
(m, [**kw	•	•	•	d with items from mapping
(m, [**kw	•	•	•	d with items from mapping or iter-
(m, [**kw	•	•	•	d with items from mapping or iter- able of
(m, [**kw	•		•	d with items from mapping or iter- able of (key,
(m, [**kw	•			d with items from mapping or iter- able of (key, value)
(m, [**kw	•	•	•	d with items from mapping or iter- able of (key, value)
(m, [**kw args])	•	•	•	d with items from mapping or iter- able of (key, value) pairs

defaultdict OrderedDict

dict

- **a** default\_factory is not a method, but a callable attribute set by the end user when a defaultdict is instantiated.
- OrderedDict.popitem(last=False) removes the first item inserted (FIFO). The last keyword argument is not supported in dict or defaul tdict as recently as Python 3.10b3.
- **©** Reversed operators are explained in Chapter 16.

The way d.update(m) handles its first argument m is a prime example of duck typing: it first checks whether m has a keys method and, if it does, assumes it is a mapping. Otherwise, update() falls back to iterating over m, assuming its items are (key, value) pairs. The constructor for most Python mappings uses the logic of update() internally, which means they can be initialized from other mappings or from any iterable object producing (key, value) pairs.

A subtle mapping method is <code>setdefault()</code> . It avoids redundant key lookups when we need to update the value of an item in place. The next section shows how to use it.

## **Inserting or Updating Mutable Values**

In line with Python's fail-fast philosophy, dict access with d[k] raises an error when k is not an existing key. Pythonistas know that d.get(k, default) is an alternative to d[k] whenever a default value is more convenient than handling KeyError. However, when you retrieve a mutable value and want to update it, there is a better way.

Consider a script to index text, producing a mapping where each key is a word, and the value is a list of positions where that word occurs, as shown in <a href="Example 3-3">Example 3-3</a>.

Example 3-3. Partial output from <a href="Example 3-4">Example 3-4</a> processing the "Zen of Python"; each line shows a word and a list of occurrences coded as pairs: (line number, column number)

```
$ python3 index0.py zen.txt
a [(19, 48), (20, 53)]
Although [(11, 1), (16, 1), (18, 1)]
ambiguity [(14, 16)]
and [(15, 23)]
are [(21, 12)]
aren [(10, 15)]
at [(16, 38)]
bad [(19, 50)]
be [(15, 14), (16, 27), (20, 50)]
beats [(11, 23)]
Beautiful [(3, 1)]
better [(3, 14), (4, 13), (5, 11), (6, 12), (7, 9), (8, 11), (17, 8), (18, 1)...
```

Example 3-4 is a suboptimal script written to show one case where dict.get is not the best way to handle a missing key. I adapted it from an example by Alex Martelli.4

Example 3-4. index0.py uses dict.get to fetch and update a list of word occurrences from the index (a better solution is in <a href="Example 3-5">Example 3-5</a>)

```
"""Build an index mapping word -> list of occurrences"""
import re
import sys
WORD RE = re.compile(r' \w+')
index = {}
with open(sys.argv[1], encoding='utf-8') as fp:
    for line no, line in enumerate (fp, 1):
        for match in WORD RE.finditer(line):
            word = match.group()
            column no = match.start() + 1
            location = (line no, column no)
            # this is ugly; coded like this to make a point
            occurrences = index.get(word, []) 0
                                               ø
            occurrences.append(location)
                                               0
            index[word] = occurrences
# display in alphabetical order
                                               0
for word in sorted(index, key=str.upper):
    print(word, index[word])
```

- Get the list of occurrences for word, or [] if not found.
- 2 Append new location to occurrences.
- **3** Put changed occurrences into index dict; this entails a second search through the index.
- In the key= argument of sorted, I am not calling str.upper, just passing a reference to that method so the sorted function can use it to normalize the words for sorting. 5

The three lines dealing with occurrences in <a href="Example 3-4">Example 3-4</a> can be replaced by a single line using dict.setdefault.</a> <a href="Example 3-5">Example 3-5</a> is closer to Alex Martelli's code.

Example 3-5. index.py uses dict.setdefault to fetch and update a list of word occurrences from the index in a single line; contrast with <a href="Example 3-4">Example 3-4</a>

```
import re
import sys

WORD_RE = re.compile(r'\w+')

index = {}

with open(sys.argv[1], encoding='utf-8') as fp:
    for line_no, line in enumerate(fp, 1):
        for match in WORD_RE.finditer(line):
            word = match.group()
            column_no = match.start() + 1
            location = (line_no, column_no)
                index.setdefault(word, []).append(location)

# display in alphabetical order
for word in sorted(index, key=str.upper):
            print(word, index[word])
```

• Get the list of occurrences for word, or set it to [] if not found; setdefault returns the value, so it can be updated without requiring a second search.

In other words, the end result of this line...

```
my_dict.setdefault(key, []).append(new_value)
```

...is the same as running...

```
if key not in my_dict:
    my_dict[key] = []
my_dict[key].append(new_value)
```

...except that the latter code performs at least two searches for key—three if it's not found—while setdefault does it all with a single lookup.

A related issue, handling missing keys on any lookup (and not only when inserting), is the subject of the next section.

# Automatic Handling of Missing Keys

Sometimes it is convenient to have mappings that return some made-up value when a missing key is searched. There are two main approaches to this: one is to use a defaultdict instead of a plain dict. The other is to subclass dict or any other mapping type and add a \_\_missing\_\_ method. Both solutions are covered next.

## defaultdict: Another Take on Missing Keys

A collections.defaultdict instance creates items with a default value on demand whenever a missing key is searched using d[k] syntax. Example 3-6 uses defaultdict to provide another elegant solution to the word index task from Example 3-5.

Here is how it works: when instantiating a defaultdict, you provide a callable to produce a default value whenever \_\_getitem\_\_ is passed a nonexistent key argument.

For example, given a defaultdict created as dd = defaultdict(list), if 'new-key' is not in dd, the expression dd['new-key'] does the following steps:

- 1. Calls list() to create a new list.
- 2. Inserts the list into dd using 'new-key' as key.
- 3. Returns a reference to that list.

The callable that produces the default values is held in an instance attribute named default\_factory.

Example 3-6. index\_default.py: using defaultdict instead of the setdefault method

```
"""Build an index mapping word -> list of occurrences"""
import collections
import re
import sys
```

```
WORD_RE = re.compile(r'\w+')

index = collections.defaultdict(list)

with open(sys.argv[1], encoding='utf-8') as fp:
    for line_no, line in enumerate(fp, 1):
        for match in WORD_RE.finditer(line):
            word = match.group()
            column_no = match.start() + 1
            location = (line_no, column_no)
            index[word].append(location)

# display in alphabetical order
for word in sorted(index, key=str.upper):
            print(word, index[word])
```

- Create a defaultdict with the list constructor as default\_factory.
- If word is not initially in the index, the default\_factory is called to produce the missing value, which in this case is an empty list that is then assigned to index[word] and returned, so the .append(location) operation always succeeds.

If no default\_factory is provided, the usual KeyError is raised for missing keys.

#### WARNING

The default\_factory of a defaultdict is only invoked to provide default values for \_\_getitem\_\_ calls, and not for the other methods. For example, if dd is a defaultdict, and k is a missing key, dd[k] will call the default\_factory to create a default value, but dd.get(k) still returns None, and k in dd is False.

The mechanism that makes defaultdict work by calling default\_factory is the \_\_missing\_\_ special method, a feature that we discuss next.

## The \_missing\_ Method

Underlying the way mappings deal with missing keys is the aptly named \_\_missing\_\_ method. This method is not defined in the base dict class, but dict is aware of it: if you subclass dict and provide a \_\_missing\_\_ method, the standard dict.\_\_getitem\_\_ will call it whenever a key is not found, instead of raising KeyError.

Suppose you'd like a mapping where keys are converted to str when looked up. A concrete use case is a device library for IoT, where a programmable board with general-purpose I/O pins (e.g., a Raspberry Pi or an Arduino) is represented by a Board class with a my\_board.pins attribute, which is a mapping of physical pin identifiers to pin software objects. The physical pin identifier may be just a number or a string like "AO" or "P9\_12". For consistency, it is desirable that all keys in board.pins are strings, but it is also convenient looking up a pin by number, as in my\_arduino.pin[13], so that beginners are not tripped when they want to blink the LED on pin 13 of their Arduinos. Example 3-7 shows how such a mapping would work.

Example 3-7. When searching for a nonstring key, StrKeyDictO converts it to str when it is not found

```
Tests for item retrieval using `d[key]` notation::
    >>> d = StrKeyDict0([('2', 'two'), ('4', 'four')])
    >>> d['2']
    'two'
    >>> d[4]
    'four'
    >>> d[1]
    Traceback (most recent call last):
    KeyError: '1'
Tests for item retrieval using `d.get(key)` notation::
    >>> d.get('2')
    'two'
    >>> d.get(4)
    'four'
    >>> d.get(1, 'N/A')
    'N/A'
Tests for the `in` operator::
```

```
>>> 2 in d
True
>>> 1 in d
False
```

Example 3-8 implements a class StrKeyDictO that passes the preceding doctests.

#### TIP

A better way to create a user-defined mapping type is to subclass collections.UserDict instead of dict (as we will do in <a href="Example 3-9">Example 3-9</a>). Here we subclass dict just to show that \_\_missing\_\_ is supported by the built-in dict.\_\_getitem\_\_ method.

# Example 3-8. StrKeyDictO converts nonstring keys to str on lookup (see tests in <a href="Example 3-7">Example 3-7</a>)

- StrKeyDict0 inherits from dict.
- **2** Check whether key is already a str. If it is, and it's missing, raise KeyError.
- 3 Build str from key and look it up.

- ◆ The get method delegates to \_\_getitem\_\_ by using the self[key] notation; that gives the opportunity for our missing to act.
- If a KeyError was raised, \_\_missing\_\_ already failed, so we return the default.
- **6** Search for unmodified key (the instance may contain non-str keys), then for a str built from the key.

Take a moment to consider why the test isinstance (key, str) is necessary in the missing implementation.

Without that test, our <code>\_\_missing\_\_</code> method would work OK for any key <code>k\_str</code> or not <code>str\_whenever</code> <code>str(k)</code> produced an existing key. But if <code>str(k)</code> is not an existing key, we'd have an infinite recursion. In the last line of <code>\_\_missing\_\_</code>, <code>self[str(key)]</code> would call <code>\_\_getitem\_\_</code>, passing that <code>str</code> key, which in turn would call <code>\_\_missing\_\_</code> again.

The \_\_contains\_\_ method is also needed for consistent behavior in this example, because the operation k in d calls it, but the method inherited from dict does not fall back to invoking \_\_missing\_\_ . There is a subtle detail in our implementation of \_\_contains\_\_ : we do not check for the key in the usual Pythonic way— k in my\_dict—because str(key) in self would recursively call \_\_contains\_\_ . We avoid this by explicitly looking up the key in self.keys().

A search like <code>k in my\_dict.keys()</code> is efficient in Python 3 even for very large mappings because <code>dict.keys()</code> returns a view, which is similar to a set, as we'll see in "Set Operations on dict Views". However, remember that <code>k in my\_dict</code> does the same job, and is faster because it avoids the attribute lookup to find the <code>.keys</code> method.

I had a specific reason to use <code>self.keys()</code> in the <code>\_\_contains\_\_</code> method in <code>Example 3-8</code>. The check for the unmodified key— <code>key in self.keys()</code>—is necessary for correctness because <code>StrKeyDictO</code> does not enforce that all keys in the dictionary must be of type <code>str.Our</code> only goal with this simple example is to make searching "friendlier" and not enforce types.

## WARNING

User-defined classes derived from standard library mappings may or may not use \_\_missing\_\_ as a fallback in their implementations of \_\_getitem\_\_, get, or \_\_contains\_\_, as explained in the next section.

# Inconsistent Usage of \_\_missing\_\_ in the Standard Library

Consider the following scenarios, and how the missing key lookups are affected:

```
dict subclass
  A subclass of dict implementing only missing and no
 other method. In this case, missing may be called only on
  d[k], which will use the getitem inherited from dict.
collections. UserDict subclass
 Likewise, a subclass of UserDict implementing only
  missing and no other method. The get method inherited
  from UserDict calls getitem . This means missing
 may be called to handle lookups with d[k] and d.get(k).
abc. Mapping subclass with the simplest possible getitem
 A minimal subclass of abc. Mapping implementing missing
  and the required abstract methods, including an implementation of
  getitem that does not call missing . The
  missing method is never triggered in this class.
abc. Mapping subclass with getitem calling missing
  A minimal subclass of abc. Mapping implementing missing
  and the required abstract methods, including an implementation of
  getitem that calls missing . The missing
  method is triggered in this class for missing key lookups made with
  d[k], d.get(k), and k in d.
```

See <u>missing.py</u> in the example code repository for demonstrations of the scenarios described here.

The four scenarios just described assume minimal implementations. If your subclass implements <code>\_\_getitem\_\_</code>, <code>get</code>, and <code>\_\_contains\_\_</code>, then you can make those methods use <code>\_\_missing\_\_</code> or not, depending on your needs. The point of this section is to show that you must be careful when subclassing standard library mappings to use <code>\_\_missing\_\_</code>, because the base classes support different behaviors by default.

Don't forget that the behavior of setdefault and update is also affected by key lookup. And finally, depending on the logic of your \_\_missing\_\_, you may need to implement special logic in \_\_setitem\_\_, to avoid inconsistent or surprising behavior. We'll see an example of this in "Subclassing UserDict Instead of dict".

So far we have covered the dict and defaultdict mapping types, but the standard library comes with other mapping implementations, which we discuss next.

## Variations of dict

In this section is an overview of mapping types included in the standard library, besides defaultdict, already covered in "defaultdict: Another Take on Missing Keys".

## collections.OrderedDict

Now that the built-in dict also keeps the keys ordered since Python 3.6, the most common reason to use OrderedDict is writing code that is backward compatible with earlier Python versions. Having said that, Python's documentation lists some remaining differences between dict and OrderedDict, which I quote here—only reordering the items for relevance in daily use:

- The equality operation for OrderedDict checks for matching order.
- The popitem() method of OrderedDict has a different signature. It accepts an optional argument to specify which item is popped.
- OrderedDict has a move\_to\_end() method to efficiently reposition an element to an endpoint.
- The regular dict was designed to be very good at mapping operations. Tracking insertion order was secondary.

- OrderedDict was designed to be good at reordering operations.
   Space efficiency, iteration speed, and the performance of update operations were secondary.
- Algorithmically, OrderedDict can handle frequent reordering operations better than dict. This makes it suitable for tracking recent accesses (for example, in an LRU cache).

## collections.ChainMap

A ChainMap instance holds a list of mappings that can be searched as one. The lookup is performed on each input mapping in the order it appears in the constructor call, and succeeds as soon as the key is found in one of those mappings. For example:

```
>>> d1 = dict(a=1, b=3)
>>> d2 = dict(a=2, b=4, c=6)
>>> from collections import ChainMap
>>> chain = ChainMap(d1, d2)
>>> chain['a']
1
>>> chain['c']
6
```

The ChainMap instance does not copy the input mappings, but holds references to them. Updates or insertions to a ChainMap only affect the first input mapping. Continuing from the previous example:

```
>>> chain['c'] = -1
>>> d1
{'a': 1, 'b': 3, 'c': -1}
>>> d2
{'a': 2, 'b': 4, 'c': 6}
```

ChainMap is useful to implement interpreters for languages with nested scopes, where each mapping represents a scope context, from the innermost enclosing scope to the outermost scope. The "ChainMap objects" section of the collections docs has several examples of ChainMap usage, including this snippet inspired by the basic rules of variable lookup in Python:

```
import builtins
pylookup = ChainMap(locals(), globals(), vars(builtins))
```

<u>Example 18-14</u> shows a ChainMap subclass used to implement an interpreter for a subset of the Scheme programming language.

### collections.Counter

A mapping that holds an integer count for each key. Updating an existing key adds to its count. This can be used to count instances of hashable objects or as a multiset (discussed later in this section). Counter implements the + and - operators to combine tallies, and other useful methods such as <code>most\_common([n])</code>, which returns an ordered list of tuples with the *n* most common items and their counts; see the <u>documentation</u>. Here is <code>Counter</code> used to count letters in words:

```
>>> ct = collections.Counter('abracadabra')
>>> ct
Counter({'a': 5, 'b': 2, 'r': 2, 'c': 1, 'd': 1})
>>> ct.update('aaaaazzz')
>>> ct
Counter({'a': 10, 'z': 3, 'b': 2, 'r': 2, 'c': 1, 'd': 1})
>>> ct.most_common(3)
[('a', 10), ('z', 3), ('b', 2)]
```

Note that the 'b' and 'r' keys are tied in third place, but ct.most common(3) shows only three counts.

To use collections. Counter as a multiset, pretend each key is an element in the set, and the count is the number of occurrences of that element in the set.

## shelve.Shelf

The shelve module in the standard library provides persistent storage for a mapping of string keys to Python objects serialized in the pickle binary format. The curious name of shelve makes sense when you realize that pickle jars are stored on shelves.

The shelve.open module-level function returns a shelve.Shelf instance—a simple key-value DBM database backed by the dbm module,

with these characteristics:

- shelve. Shelf subclasses abc. Mutable Mapping, so it provides the essential methods we expect of a mapping type.
- In addition, shelve. Shelf provides a few other I/O management methods, like sync and close.
- A Shelf instance is a context manager, so you can use a with block to make sure it is closed after use.
- Keys and values are saved whenever a new value is assigned to a key.
- The keys must be strings.
- The values must be objects that the pickle module can serialize.

The documentation for the <u>shelve</u>, <u>dbm</u>, and <u>pickle</u> modules provides more details and some caveats.

#### WARNING

Python's pickle is easy to use in the simplest cases, but has several drawbacks. Read Ned Batchelder's <u>"Pickle's nine flaws"</u> before adopting any solution involving pickle. In his post, Ned mentions other serialization formats to consider.

OrderedDict, ChainMap, Counter, and Shelf are ready to use but can also be customized by subclassing. In contrast, UserDict is intended only as a base class to be extended.

## **Subclassing UserDict Instead of dict**

It's better to create a new mapping type by extending collections. UserDict rather than dict. We realize that when we try to extend our StrKeyDictO from <a href="Example 3-8">Example 3-8</a> to make sure that any keys added to the mapping are stored as str.

The main reason why it's better to subclass UserDict rather than dict is that the built-in has some implementation shortcuts that end up forcing us to override methods that we can just inherit from UserDict with no problems. $^{7}$ 

Note that UserDict does not inherit from dict, but uses composition: it has an internal dict instance, called data, which holds the actual

items. This avoids undesired recursion when coding special methods like \_\_setitem\_\_, and simplifies the coding of \_\_contains\_\_, compared to Example 3-8.

Thanks to UserDict, StrKeyDict (Example 3-9) is more concise than StrKeyDictO (Example 3-8), but it does more: it stores all keys as str, avoiding unpleasant surprises if the instance is built or updated with data containing nonstring keys.

Example 3-9. StrkeyDict always converts nonstring keys to str on insertion, update, and lookup

```
import collections
class StrKeyDict(collections.UserDict): 0
    def missing (self, key): 2
        if isinstance(key, str):
            raise KeyError(key)
        return self[str(key)]
    def contains (self, key):
        return str(key) in self.data 3
    def setitem (self, key, item):
        self.data[str(kev)] = item
1 StrKeyDict extends UserDict.
  missing is exactly as in Example 3-8.
3 contains is simpler: we can assume all stored keys are str,
  and we can check on self.data instead of invoking
  self.keys() as we did in StrKeyDict0.
```

• \_\_setitem\_\_ converts any key to a str. This method is easier to overwrite when we can delegate to the self.data attribute.

Because UserDict extends abc.MutableMapping, the remaining methods that make StrKeyDict a full-fledged mapping are inherited from UserDict, MutableMapping, or Mapping. The latter have sev-

eral useful concrete methods, in spite of being abstract base classes (ABCs). The following methods are worth noting:

MutableMapping.update

This powerful method can be called directly but is also used by \_\_init\_\_ to load the instance from other mappings, from iterables of (key, value) pairs, and keyword arguments. Because it uses self[key] = value to add items, it ends up calling our implementation of setitem .

Mapping.get

In StrKeyDict0 (Example 3-8), we had to code our own get to return the same results as \_\_getitem\_\_, but in Example 3-9 we inherited Mapping.get, which is implemented exactly like StrKeyDict0.get (see the Python source code).

TIP

Antoine Pitrou authored <u>PEP 455—Adding a key-transforming dictionary to collections</u> and a patch to enhance the collections module with a TransformDict, that is more general than StrKeyDict and preserves the keys as they are provided, before the transformation is applied. PEP 455 was rejected in May 2015—see Raymond Hettinger's <u>rejection message</u>. To experiment with TransformDict, I extracted Pitrou's patch from <u>issue18986</u> into a standalone module (<u>03-dict-set/transformdict.py</u> in the <u>Fluent Python</u> second edition code repository).

We know there are immutable sequence types, but how about an immutable mapping? Well, there isn't a real one in the standard library, but a stand-in is available. That's next.

# Immutable Mappings

The mapping types provided by the standard library are all mutable, but you may need to prevent users from changing a mapping by accident. A concrete use case can be found, again, in a hardware programming library like *Pingo*, mentioned in "The missing Method": the board.pins mapping represents the physical GPIO pins on the device. As such, it's useful to prevent inadvertent updates to board.pins because the hardware can't be changed via software, so any change in the

mapping would make it inconsistent with the physical reality of the device.

The types module provides a wrapper class called MappingProxyType, which, given a mapping, returns a mappingproxy instance that is a read-only but dynamic proxy for the original mapping. This means that updates to the original mapping can be seen in the mappingproxy, but changes cannot be made through it. See <a href="Example 3-10">Example 3-10</a> for a brief demonstration.

**Example 3-10.** MappingProxyType **builds a read-only** mappingproxy **instance from a** dict

```
>>> from types import MappingProxyType
>>> d = {1: 'A'}
>>> d proxy = MappingProxyType(d)
>>> d proxy
mappingproxy({1: 'A'})
>>> d proxy[1] 1
'A'
>>> d proxy[2] = 'x' 2
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: 'mappingproxy' object does not support item assignment
>>> d[2] = 'B'
>>> d proxy 3
mappingproxy({1: 'A', 2: 'B'})
>>> d proxy[2]
'B'
>>>
```

- Items in d can be seen through d\_proxy.
- Changes cannot be made through d\_proxy.
- **3** d\_proxy is dynamic: any change in d is reflected.

Here is how this could be used in practice in the hardware programming scenario: the constructor in a concrete Board subclass would fill a private mapping with the pin objects, and expose it to clients of the API via a public .pins attribute implemented as a mappingproxy. That way the clients would not be able to add, remove, or change pins by accident.

Next, we'll cover views—which allow high-performance operations on a dict, without unnecessary copying of data.

# **Dictionary Views**

The dict instance methods .keys(), .values(), and .items() return instances of classes called dict\_keys, dict\_values, and dict\_items, respectively. These dictionary views are read-only projections of the internal data structures used in the dict implementation. They avoid the memory overhead of the equivalent Python 2 methods that returned lists duplicating data already in the target dict, and they also replace the old methods that returned iterators.

<u>Example 3-11</u> shows some basic operations supported by all dictionary views.

Example 3-11. The .values() method returns a view of the values in a dict

- The repr of a view object shows its content.
- 2 We can query the len of a view.
- 3 Views are iterable, so it's easy to create lists from them.
- Views implement \_\_reversed\_\_, returning a custom iterator.

**6** We can't use [] to get individual items from a view.

A view object is a dynamic proxy. If the source dict is updated, you can immediately see the changes through an existing view. Continuing from Example 3-11:

```
>>> d['z'] = 99
>>> d
{'a': 10, 'b': 20, 'c': 30, 'z': 99}
>>> values
dict_values([10, 20, 30, 99])
```

The classes dict\_keys, dict\_values, and dict\_items are internal: they are not available via \_\_builtins\_\_ or any standard library module, and even if you get a reference to one of them, you can't use it to create a view from scratch in Python code:

```
>>> values_class = type({}.values())
>>> v = values_class()
Traceback (most recent call last):
   File "<stdin>", line 1, in <module>
TypeError: cannot create 'dict_values' instances
```

The dict\_values class is the simplest dictionary view—it implements only the \_\_len\_\_, \_\_iter\_\_, and \_\_reversed\_\_ special methods. In addition to these methods, dict\_keys and dict\_items implement several set methods, almost as many as the frozenset class. After we cover sets, we'll have more to say about dict\_keys and dict\_items in "Set Operations on dict Views".

Now let's see some rules and tips informed by the way dict is implemented under the hood.

# Practical Consequences of How dict Works

The hash table implementation of Python's dict is very efficient, but it's important to understand the practical effects of this design:

- Keys must be hashable objects. They must implement proper
   \_\_hash\_\_ and \_\_eq\_\_ methods as described in "What Is Hashable".
- Item access by key is very fast. A dict may have millions of keys, but Python can locate a key directly by computing the hash code of the key and deriving an index offset into the hash table, with the possible overhead of a small number of tries to find a matching entry.
- Key ordering is preserved as a side effect of a more compact memory layout for dict in CPython 3.6, which became an official language feature in 3.7.
- Despite its new compact layout, dicts inevitably have a significant memory overhead. The most compact internal data structure for a container would be an array of pointers to the items. Compared to that, a hash table needs to store more data per entry, and Python needs to keep at least one-third of the hash table rows empty to remain efficient.
- To save memory, avoid creating instance attributes outside of the
   \_\_init\_\_ method.

That last tip about instance attributes comes from the fact that Python's default behavior is to store instance attributes in a special \_\_dict\_\_ attribute, which is a dict attached to each instance. Since PEP 412—Key-Sharing Dictionary was implemented in Python 3.3, instances of a class can share a common hash table, stored with the class. That common hash table is shared by the \_\_dict\_\_ of each new instance that has the same attributes names as the first instance of that class when \_\_init\_\_ returns. Each instance \_\_dict\_\_ can then hold only its own attribute values as a simple array of pointers. Adding an instance attribute after \_\_init\_\_ forces Python to create a new hash table just for the \_\_dict\_\_ of that one instance (which was the default behavior for all instances before Python 3.3). According to PEP 412, this optimization reduces memory use by 10% to 20% for object-oriented programs.

The details of the compact layout and key-sharing optimizations are rather complex. For more, please read <u>"Internals of sets and dicts"</u> at <u>fluentpython.com</u>.

Now let's dive into sets.

# Set Theory

Sets are not new in Python, but are still somewhat underused. The set type and its immutable sibling frozenset first appeared as modules in the Python 2.3 standard library, and were promoted to built-ins in Python 2.6.

#### NOTE

In this book, I use the word "set" to refer both to set and frozenset. When talking specifically about the set class, I use constant width font: set.

A set is a collection of unique objects. A basic use case is removing duplication:

```
>>> l = ['spam', 'spam', 'eggs', 'spam', 'bacon', 'eggs']
>>> set(l)
{'eggs', 'spam', 'bacon'}
>>> list(set(l))
['eggs', 'spam', 'bacon']
```

#### TIP

If you want to remove duplicates but also preserve the order of the first occurrence of each item, you can now use a plain dict to do it, like this:

```
>>> dict.fromkeys(l).keys()
dict_keys(['spam', 'eggs', 'bacon'])
>>> list(dict.fromkeys(l).keys())
['spam', 'eggs', 'bacon']
```

Set elements must be hashable. The set type is not hashable, so you can't build a set with nested set instances. But frozenset is hashable, so you can have frozenset elements inside a set.

In addition to enforcing uniqueness, the set types implement many set operations as infix operators, so, given two sets a and b,  $a \mid b$  returns their union,  $a \notin b$  computes the intersection, a - b the difference, and  $a \land b$  the symmetric difference. Smart use of set operations can reduce both the line count and the execution time of Python programs, at

the same time making code easier to read and reason about—by removing loops and conditional logic.

For example, imagine you have a large set of email addresses (the haystack) and a smaller set of addresses (the needles) and you need to count how many needles occur in the haystack. Thanks to set intersection (the & operator) you can code that in a simple line (see Example 3-12).

# Example 3-12. Count occurrences of needles in a haystack, both of type set

```
found = len(needles & haystack)
```

Without the intersection operator, you'd have to write <u>Example 3-13</u> to accomplish the same task as <u>Example 3-12</u>.

# Example 3-13. Count occurrences of needles in a haystack (same end result as **Example 3-12**)

```
found = 0
for n in needles:
    if n in haystack:
        found += 1
```

Example 3-12 runs slightly faster than Example 3-13. On the other hand, Example 3-13 works for any iterable objects needles and haystack, while Example 3-12 requires that both be sets. But, if you don't have sets on hand, you can always build them on the fly, as shown in Example 3-14.

# Example 3-14. Count occurrences of needles in a haystack; these lines work for any iterable types

```
found = len(set(needles) & set(haystack))

# another way:
found = len(set(needles).intersection(haystack))
```

Of course, there is an extra cost involved in building the sets in <a href="Example 3-14"><u>Example 3-14</u></a>, but if either the needles or the haystack is already a set, the alternatives in <a href="Example 3-14"><u>Example 3-14</u></a> may be cheaper than <a href="Example 3-13"><u>Example 3-13</u></a>.

Any one of the preceding examples are capable of searching 1,000 elements in a haystack of 10,000,000 items in about 0.3 milliseconds—that's close to 0.3 microseconds per element.

Besides the extremely fast membership test (thanks to the underlying hash table), the set and frozenset built-in types provide a rich API to create new sets or, in the case of set, to change existing ones. We will discuss the operations shortly, but first a note about syntax.

### **Set Literals**

The syntax of set literals— $\{1\}$ ,  $\{1, 2\}$ , etc.—looks exactly like the math notation, with one important exception: there's no literal notation for the empty set, so we must remember to write set().

#### SYNTAX QUIRK

Don't forget that to create an empty set, you should use the constructor without an argument: set(). If you write  $\{\}$ , you're creating an empty dict—this hasn't changed in Python 3.

In Python 3, the standard string representation of sets always uses the {...} notation, except for the empty set:

```
>>> s = {1}
>>> type(s)
<class 'set'>
>>> s
{1}
>>> s.pop()
1
>>> s
set()
```

Literal set syntax like  $\{1, 2, 3\}$  is both faster and more readable than calling the constructor (e.g., set([1, 2, 3])). The latter form is slower because, to evaluate it, Python has to look up the set name to fetch the constructor, then build a list, and finally pass it to the constructor. In contrast, to process a literal like  $\{1, 2, 3\}$ , Python runs a specialized BUILD\_SET bytecode. 10

There is no special syntax to represent frozenset literals—they must be created by calling the constructor. The standard string representation in Python 3 looks like a frozenset constructor call. Note the output in the console session:

```
>>> frozenset(range(10))
frozenset({0, 1, 2, 3, 4, 5, 6, 7, 8, 9})
```

Speaking of syntax, the idea of listcomps was adapted to build sets as well.

## **Set Comprehensions**

Set comprehensions (*setcomps*) were added way back in Python 2.7, together with the dictcomps that we saw in <u>"dict Comprehensions"</u>. <u>Example 3-15</u> shows how.

Example 3-15. Build a set of Latin-1 characters that have the word "SIGN" in their Unicode names

- Import name function from unicodedata to obtain character names.
- Build set of characters with codes from 32 to 255 that have the word 'SIGN' in their names.

The order of the output changes for each Python process, because of the salted hash mentioned in <u>"What Is Hashable"</u>.

Syntax matters aside, let's now consider the behavior of sets.

## Practical Consequences of How Sets Work

The set and frozenset types are both implemented with a hash table. This has these effects:

- Set elements must be hashable objects. They must implement proper
   \_\_hash\_\_\_ and \_\_eq\_\_\_ methods as described in "What Is

   Hashable".
- Membership testing is very efficient. A set may have millions of elements, but an element can be located directly by computing its hash code and deriving an index offset, with the possible overhead of a small number of tries to find a matching element or exhaust the search.
- Sets have a significant memory overhead, compared to a low-level array pointers to its elements—which would be more compact but also much slower to search beyond a handful of elements.
- Element ordering depends on insertion order, but not in a useful or reliable way. If two elements are different but have the same hash code, their position depends on which element is added first.
- Adding elements to a set may change the order of existing elements.
   That's because the algorithm becomes less efficient if the hash table is more than two-thirds full, so Python may need to move and resize the table as it grows. When this happens, elements are reinserted and their relative ordering may change.

See "Internals of sets and dicts" at *fluentpython.com* for details.

Let's now review the rich assortment of operations provided by sets.

## **Set Operations**

Figure 3-2 gives an overview of the methods you can use on mutable and immutable sets. Many of them are special methods that overload operators, such as & and >=. Table 3-2 shows the math set operators that have corresponding operators or methods in Python. Note that some operators and methods perform in-place changes on the target set (e.g., &=, difference\_update, etc.). Such operations make no sense in the ideal world of mathematical sets, and are not implemented in frozenset.

#### TIP

The infix operators in <u>Table 3-2</u> require that both operands be sets, but all other methods take one or more iterable arguments. For example, to produce the union of four collections, a, b, c, and d, you can call a.union(b, c, d), where a must be a set, but b, c, and d can be iterables of any type that produce hashable items. If you need to create a new set with the union of four iterables, instead of updating an existing set, you can write  $\{*a, *b, *c, *d\}$  since Python 3.5 thanks to <u>PEP 448—Additional Unpacking Generalizations</u>.

Figure 3-2. Simplified UML class diagram for MutableSet and its superclasses from collections.abc (names in italic are abstract classes and abstract methods; reverse operator methods omitted for brevity).

Table 3-2. Mathematical set operations: these methods either produce a new set or update the target set in place, if it's mutable

Math symbol	Python operator	Method	Description
$S\capZ$	s & z	sand (z)	Intersection of s and z
	z & s	srand (z)	Reversed & operator
		<pre>s.intersec tion(it,)</pre>	
	s &= z	siand (z)	s updated with intersection of s and z
		<pre>s.intersec tion_updat e(it,)</pre>	tion of s and all sets built
S U Z	s   z	sor (z)	Union of s and z
	z   s	sror (z)	Reversed
		s.union(i t,)	Union of $ {\tt s} $ and all sets built from iterables $ {\tt it} $ , etc.
	s  = z	sior (z)	s updated with union of s and z
		s.update(i t,)	s updated with union of s and all sets built from iterables it, etc.

Math symbol	Python operator	Method	Description
$S \setminus Z$	s - z	ssub (z)	Relative complement or difference between s and z
	z - s	srsub (z)	Reversed – operator
		s.differen ce(it,)	
	s -= z	sisub (z)	${\tt s}$ updated with difference between ${\tt s}$ and ${\tt z}$
		<pre>s.differen ce_update (it,)</pre>	s updated with difference between s and all sets built from iterables ${\tt it}$ , etc.
SΔZ	s ^ z	sxor (z)	Symmetric difference (the complement of the intersection $s \& z$ )
	z ^ s	srxor (z)	Reversed ^ operator
		<pre>s.symmetri c_differen ce(it)</pre>	Complement of s & set (it)
	s ^= z	sixor (z)	${\tt s}$ updated with symmetric difference of ${\tt s}$ and ${\tt z}$

Math symbol	Python operator	Method	Description	
		<pre>s.symmetri c_differen ce_update (it,)</pre>	s updated with symmetric difference of s and all sets built from iterables it, etc.	

 $\underline{\textbf{Table 3-3}}$  lists set predicates: operators and methods that return  $\,\, \texttt{True} \,\,\, \texttt{or} \,\,\,$  False.

Table 3-3. Set comparison operators and methods that return a bool

Math symbol	Python operator	Method	Description
S ∩ Z = Ø		_	s and z are disjoint (no elements in common)
$e \in S$	e in s	scont ains (e)	Element e is a member of s
$S \subseteq Z$	s <= z	sle (z)	s is a subset of the z set
		s.issubs et(it)	s is a subset of the set built from the iterable it
$S \subset Z$	s < z		s is a proper subset of the z set
$S \supseteq Z$	s >= z	sge (z)	s is a superset of the z set
		s.issupe rset(it)	s is a superset of the set built from the iterable it
$S \supset Z$	s > z	sgt (z)	s is a proper superset of the z set

In addition to the operators and methods derived from math set theory, the set types implement other methods of practical use, summarized in Table 3-4.

	set	frozenset	
s.add (e)	•		Add element e to s
s.clea r()	•		Remove all elements of s
s.copy	•	•	Shallow copy of s
s.disc ard(e)	•		Remove element e from s if it is present
sit er()	•	•	Get iterator over s
sle n()	•	•	len(s)
s.pop	•		Remove and return an element from s, raising KeyError if s is empty
s.remo ve(e)	•		Remove element e from s, raising KeyError if e not i n s

This completes our overview of the features of sets. As promised in "<u>Dictionary Views</u>", we'll now see how two of the dictionary view types behave very much like a frozenset.

## Set Operations on dict Views

	frozenset	dict_keys	dict_items	Description
sand_ _(z)	•	•	•	s & z (in- tersection of s and z)
srand (z)	•	•	•	Reversed & operator
scont ains()	•	•	•	e in s
s.copy()	•			Shallow copy of s
s.differ ence(it,)	•			Difference between s and iter- ables it, etc.
s.inters ection(i t,)	•			Intersection of s and iterables it, etc.
s.isdisj	•	•	•	s and z are disjoint (no ele- ments in common)
s.issubs et(it)	•			s is a sub- set of iter- able it

	frozenset	dict_keys	dict_items	Description
s.issupe rset(it)	•			s is a su- perset of it- erable it
siter ()	•	•	•	Get iterator over s
slen_ _()	•	•	•	len(s)
sor (z)	•	•	•	s   z (union of s and z)
sror_ _()	•	•	•	Reversed   operator
sreve rsed()		•	•	Get iterator over s in reverse order
srsub (z)	•	•	•	Reversed – operator
ssub_ _(z)	•	•	•	s - z (difference between s and z)
<pre>s.symmet ric_diffe rence(i t)</pre>	•			Complement of s & set (it)

In particular, dict\_keys and dict\_items implement the special methods to support the powerful set operators & (intersection), | (union), - (difference), and ^ (symmetric difference).

For example, using  $\alpha$  is easy to get the keys that appear in two dictionaries:

```
>>> d1 = dict(a=1, b=2, c=3, d=4)

>>> d2 = dict(b=20, d=40, e=50)

>>> d1.keys() & d2.keys()

{'b', 'd'}
```

Note that the return value of  $\,\&\,$  is a  $\,$ set  $\,$ . Even better: the set operators in dictionary views are compatible with  $\,$ set  $\,$ instances. Check this out:

```
>>> s = {'a', 'e', 'i'}
>>> d1.keys() & s
{'a'}
>>> d1.keys() | s
{'a', 'c', 'b', 'd', 'i', 'e'}
```

#### WARNING

A dict\_items view only works as a set if all values in the dict are hashable. Attempting set operations on a dict\_items view with an unhashable value raises TypeError: unhashable type 'T', with T as the type of the offending value.

On the other hand, a dict\_keys view can always be used as a set, because every key is hashable—by definition.

Using set operators with views will save a lot of loops and ifs when inspecting the contents of dictionaries in your code. Let Python's efficient implementation in C work for you!

With this, we can wrap up this chapter.

## **Chapter Summary**

Dictionaries are a keystone of Python. Over the years, the familiar  $\{k1: v1, k2: v2\}$  literal syntax was enhanced to support unpacking with \*\*, pattern matching, as well as dict comprehensions.

Beyond the basic dict, the standard library offers handy, ready-to-use specialized mappings like defaultdict, ChainMap, and Counter, all defined in the collections module. With the new dict implementation, OrderedDict is not as useful as before, but should remain in the standard library for backward compatibility—and has specific characteristics that dict doesn't have, such as taking into account key ordering in == comparisons. Also in the collections module is the UserDict, an easy to use base class to create custom mappings.

Two powerful methods available in most mappings are setdefault and update. The setdefault method can update items holding mutable values—for example, in a dict of list values—avoiding a second search for the same key. The update method allows bulk insertion or overwriting of items from any other mapping, from iterables providing (key, value) pairs, and from keyword arguments. Mapping constructors also use update internally, allowing instances to be initialized from mappings, iterables, or keyword arguments. Since Python 3.9, we can also

use the  $\parallel$  = operator to update a mapping, and the  $\parallel$  operator to create a new one from the union of two mappings.

A clever hook in the mapping API is the \_\_missing\_\_ method, which lets you customize what happens when a key is not found when using the d[k] syntax that invokes \_\_getitem\_\_.

The collections.abc module provides the Mapping and MutableMapping abstract base classes as standard interfaces, useful for runtime type checking. The MappingProxyType from the types module creates an immutable façade for a mapping you want to protect from accidental change. There are also ABCs for Set and MutableSet.

Dictionary views were a great addition in Python 3, eliminating the memory overhead of the Python 2 .keys(), .values(), and .items() methods that built lists duplicating data in the target dict instance. In addition, the dict\_keys and dict\_items classes support the most useful operators and methods of frozenset.

## Further Reading

In The Python Standard Library documentation, "collections—Container datatypes", includes examples and practical recipes with several mapping types. The Python source code for the module <code>Lib/collections/\_init\_.py</code> is a great reference for anyone who wants to create a new mapping type or grok the logic of the existing ones. Chapter 1 of the <code>Python Cookbook</code>, <code>3rd ed</code>. (O'Reilly) by David Beazley and Brian K. Jones has 20 handy and insightful recipes with data structures—the majority using <code>dict</code> in clever ways.

Greg Gandenberger advocates for the continued use of collections.OrderedDict, on the grounds that "explicit is better than implicit," backward compatibility, and the fact that some tools and libraries assume the ordering of dict keys is irrelevant—his post: "Python Dictionaries Are Now Ordered. Keep Using OrderedDict".

<u>PEP 3106—Revamping dict.keys(), .values()</u> and .items() is where Guido van Rossum presented the dictionary views feature for Python 3. In the abstract, he wrote that the idea came from the Java Collections Framework.

<u>PyPy</u> was the first Python interpreter to implement Raymond Hettinger's proposal of compact dicts, and they blogged about it in <u>"Faster, more memory efficient and more ordered dictionaries on PyPy"</u>, acknowledging that a similar layout was adopted in PHP 7, described in <u>PHP's new hashtable implementation</u>. It's always great when creators cite prior art.

At PyCon 2017, Brandon Rhodes presented <u>"The Dictionary Even</u> Mightier", a sequel to his classic animated presentation <u>"The Mighty Dictionary"</u>—including animated hash collisions! Another up-to-date, but more in-depth video on the internals of Python's dict is <u>"Modern Dictionaries"</u> by Raymond Hettinger, where he tells that after initially failing to sell compact dicts to the CPython core devs, he lobbied the PyPy team, they adopted it, the idea gained traction, and was finally <u>contributed</u> to CPython 3.6 by INADA Naoki. For all details, check out the extensive comments in the CPython code for <u>Objects/dictobject.c</u> and the design document <u>Objects/dictnotes.txt</u>.

Adding a Built-In Set Object Type. When PEP 218 was approved, no special literal syntax was adopted for sets. The set literals were created for Python 3 and backported to Python 2.7, along with dict and set comprehensions. At PyCon 2019, I presented "Set Practice: learning from Python's set types" describing use cases of sets in real programs, covering their API design, and the implementation of <a href="maintenance">uintset</a>, a set class for integer elements using a bit vector instead of a hash table, inspired by an example in Chapter 6 of the excellent <a href="maintenance">The Go Programming Language</a>, by Alan Donovan and Brian Kernighan (Addison-Wesley).

IEEE's *Spectrum* magazine has a story about Hans Peter Luhn, a prolific inventor who patented a punched card deck to select cocktail recipes depending on ingredients available, among other diverse inventions including...hash tables! See "Hans Peter Luhn and the Birth of the Hashing Algorithm".

# SOAPBOX Syntactic Sugar My friend Geraldo Cohen once remarked that Python is "simple and correct."

Programming language purists like to dismiss syntax as unimportant.

#### —Alan Perlis

Syntax is the user interface of a programming language, so it does matter in practice.

Before finding Python, I did some web programming using Perl and PHP. The syntax for mappings in these languages is very useful, and I badly miss it whenever I have to use Java or C.

A good literal syntax for mappings is very convenient for configuration, table-driven implementations, and to hold data for prototyping and testing. That's one lesson the designers of Go learned from dynamic languages. The lack of a good way to express structured data in code pushed the Java community to adopt the verbose and overly complex XML as a data format.

JSON was proposed as <u>"The Fat-Free Alternative to XML"</u> and became a huge success, replacing XML in many contexts. A concise syntax for lists and dictionaries makes an excellent data interchange format.

PHP and Ruby imitated the hash syntax from Perl, using => to link keys to values. JavaScript uses : like Python. Why use two characters when one is readable enough?

JSON came from JavaScript, but it also happens to be an almost exact subset of Python syntax. JSON is compatible with Python except for the spelling of the values true, false, and null.

Armin Ronacher <u>tweeted</u> that he likes to hack Python's global namespace to add JSON-compatible aliases for Python's True, False, and None so he can paste JSON directly in the console. The basic idea:

```
>>> true, false, null = True, False, None
>>> fruit = {
... "type": "banana",
... "avg_weight": 123.2,
... "edible_peel": false,
... "species": ["acuminata", "balbisiana", "paradisiaca"],
... "issues": null,
... }
>>> fruit
```

```
{'type': 'banana', 'avg_weight': 123.2, 'edible_peel': False,
'species': ['acuminata', 'balbisiana', 'paradisiaca'], 'issues': None}
```

The syntax everybody now uses for exchanging data is Python's dict and list syntax. Now we have the nice syntax with the convenience of preserved insertion order.

Simple and correct.

- **1** A virtual subclass is any class registered by calling the <code>.register()</code> method of an ABC, as explained in "A Virtual Subclass of an ABC". A type implemented via Python/C API is also eligible if a specific marker bit is set. See

  Py\_TPFLAGS\_MAPPING.
- 2 The <u>Python Glossary</u> entry for "hashable" uses the term "hash value" instead of hash code. I prefer hash code because that is a concept often discussed in the context of mappings, where items are made of keys and values, so it may be confusing to mention the hash code as a value. In this book, I only use hash code.
- **3** See <u>PEP 456—Secure and interchangeable hash algorithm</u> to learn about the security implications and solutions adopted.
- 4 The original script appears in slide 41 of Martelli's <u>"Re-learning Python" presentation</u>. His script is actually a demonstration of dict.setdefault, as shown in our <u>Example 3-5</u>.
- 5 This is an example of using a method as a first-class function, the subject of <a href="Chapter 7">Chapter 7</a>.
- **6** One such library is <u>Pingo.io</u>, no longer under active development.
- 7 The exact problem with subclassing dict and other built-ins is covered in "Subclassing Built-In Types Is Tricky".
- **8** That's how tuples are stored.
- Unless the class has a \_\_slots\_\_ attribute, as explained in <u>"Saving Memory with slots"</u>.
- 10 This may be interesting, but is not super important. The speed up will happen only when a set literal is evaluated, and that happens at most once per Python process—when a module is initially compiled. If you're curious, import the dis

function from the  $\mbox{dis}$  module and use it to disassemble the bytecodes for a  $\mbox{set}$  literal—e.g.,  $\mbox{dis}('\{1\}')$ —and a  $\mbox{set}$  call— $\mbox{dis}('\mbox{set}([1])')$
